

# Long-Run Carbon Consumption Risks

## Model And Asset Prices

Stéphane N'Dri \*

Job Market Paper

This draft : December 23, 2021

Latest version

### Abstract

This paper analyzes how carbon risks affect the stochastic discount factor (SDF). The consumption-based carbon risk measure is based on information on aggregate consumption and carbon footprint for each good and service. Consumption growth is decomposed into two components- the growth rate of carbon consumption and the growth rate of the share of carbon consumption out of total consumption. A long-run risks model is developed where the SDF is affected by the green and carbon shocks through consumption. This paper argues that the long-run risk in the consumption growth comes mainly from the carbon consumption growth due to policies and actions to curb the emissions such as Paris Agreement and COP26. The presence of carbon consumption growth in the model helps detect the long-run risk in consumption. The model explains the cross-section of industry-level returns based on their exposures to the two risk factors I constructed, carbon consumption growth risk and the share of carbon consumption out of total consumption growth risk. This disentangling could lead to identifying industries or firms which pollute the most and constructing an investment strategy that minimizes/maximizes a long-term environmental criterion.

# Introduction

Regulators are increasingly worried about the extent to which stock markets efficiently price climate change risks and the discount rate that should be used to evaluate investments' uncertain future benefits. In fact, part of these risks is stemming from the transition process to a low-carbon economy. More precisely, to curb the carbon dioxide (CO<sub>2</sub>) emissions, climate policy aims to hold the increase of the average global temperature within 2°C of pre-industrial levels. There is a burgeoning climate finance literature that examines the efficiency of capital markets in pricing risks associated with climate change. For a detailed recent literature review, see [Hong et al. \(2020\)](#) and [Giglio et al. \(2020\)](#).

However, this market price related to carbon emissions is narrowly confined at the production<sup>1</sup> level and neglects carbon leakage inside and outside a given boundary. Carbon leakage alludes to the situation that may take place if, for any reasons of costs related to climate actions, firms were to transfer production to other countries with fewer constraints in terms of pollution. This delocalization of the production activities could lead to an increase in the total emissions of the corresponding firm. Thus, the production-based market price of carbon emissions measures incorrectly the actual impact of the carbon emissions. Moreover, as it is depicted in Figure 1, since 1998, carbon emissions in the United States measured using the consumption-based approach are consistently larger than those measured by the production based approach. Hence, the use of production-based emissions shrinks the real carbon dioxide emissions

I am really grateful to my advisor, René Garcia for his invaluable guidance during my Ph.D.. I would also like to thank Vasia Panousi, Solo Zerbo, Evan Jo for extremely useful comments and discussions. I thank members of students workshop at the Université de Montréal. I thank the following conferences where I received interesting comments: CREEA, IPhDSSC, AFES.

<sup>1</sup> The production-based carbon emissions (PCE) is exclusively referring to emissions generated at the point of production, that is, emissions physically produced

in the atmosphere. Despite this fact, most papers and climate policies focus on the production side. This paper addresses this issue by providing a new consumption-based carbon emissions (CCE) measure using 12 consumption categories. There are two benefits of using the consumption-based carbon emissions approach. First, it captures carbon leakage. Second, it captures the life-cycle of greenhouse gases (GHG) emissions expressed in carbon dioxide equivalent. The life cycle assessment gives a more complete picture of a product’s environmental impacts. It tells us about which parts of its life cycle period, the product most negatively impacts the environment.

Climate change is a long horizon phenomenon. But our actions today can help mitigate and adapt to that forthcoming risk. Our mitigation and adaptation actions will be efficient if we have a deep understanding of that long-run risk. To better understand the climate change effects on the economy, we need a long-run risks model. However, the canonical long-run risks (LRR) model studied by [Bansal and Yaron \(2004\)](#) is not suitable to analyze climate risk. First, because the dynamic of the consumption growth rate in the canonical LRR model is not directly affected by any climate-related variable. Second, because it is difficult to detect the long-run risk in the consumption coming from the canonical model ([Bansal et al. \(2007a\)](#), [Bansal et al. \(2007b\)](#), [Pohl et al. \(2018\)](#), [Schorfheide et al. \(2018\)](#) among others). Therefore, we need a new long-run risks model which specifies the consumption growth rate dynamic such that the long-run risk is easily detectable, and the consumption growth is directly affected by climate-related shocks. This paper proposes such a model based on insight from [Bansal et al. \(2016b\)](#), [Bansal et al. \(2017\)](#), and [Giglio et al. \(2021\)](#).

This paper adds two contributions to the existing literature. First, I use novel data to provide a consumption-based carbon emissions measure. Second, I introduce a long-run carbon-consumption risks model, which departs from the existing long-run risks model by the decomposition of the consumption growth into two components and by its ability to study the effects of environmental policies on asset prices, and on households’ consumption. The first component captures the effect of carbon consump-

tion on aggregate consumption and the second component captures the effect of green consumption.

To that end, this paper links the carbon footprint information of each good and service from the Economic Input-Output Life Cycle Assessment (EIO-LCA) database and the aggregate consumption information of the same goods and services from the National Income and Product Accounts (NIPA) consumption data to construct our consumption-based carbon dioxide emissions measure. To my knowledge, this paper is the first to link the NIPA and the EIO-LCA data to provide a consumption-based carbon emissions. Then, I use industry-level returns data from Kenneth R. French website to test empirically the long-run carbon consumption risks model.

To assess the impact of climate change on macro-financial variables such as dividend growth, equity premium, consumption growth, etc., this paper decomposes the consumption growth rate into two components: the carbon consumption growth component, and the share of carbon consumption growth component. In our setting, "*carbon consumption risk*" occurs for two main reasons. First, carbon risk stems from regulator willingness to curb carbon emissions at the pre-industrial level which in turn may affect future household consumption that heavily depends on carbon consumption. Second, carbon consumption creates damages through the lens of climate change. As a result, there are potential long-run risks for carbon-based consumption in both cases. Building on this insight, we theoretically characterize and then quantify carbon price risk in an asset pricing model with long-run risks in carbon consumption. This paper argues that the long-run risk in the consumption growth comes mainly from the carbon consumption growth due to policies and actions to curb the emissions such as the Paris Agreement and COP26. I hypothesize that the growth rate of the share of carbon consumption out of the total consumption does not contain any long-run risks.

This article is related to the strand of literature on the long-run risks model. Papers here include [Bansal and Yaron \(2004\)](#), [Bansal et al. \(2007a\)](#), [Bansal et al.](#)

(2007b), Koijen et al. (2010), Bonomo et al. (2011), Constantinides and Ghosh (2011), Schorfheide et al. (2018), Pohl et al. (2018), Pohl et al. (2021), etc. They modeled the consumption growth dynamic as containing a small predictable component. In those cited papers, the long-run risks come from the aggregate consumption growth rate and the economy is governed by two state variables - the expected consumption growth and the conditional volatility of the consumption growth. They find that the expected consumption growth is highly persistent, and the long-run risks are difficult to detect. To depart from this literature, I consider a new consumption growth dynamic allowing to study the effects of environmental policies on asset prices, and on households' consumption beyond the usual effects analyzed by the canonical LRR model. I decompose the consumption growth rate into two parts: a carbon growth component which creates the long-run growth risk, and a share of carbon growth component which does not create any long-run risk but affects the dynamic of the consumption growth and acts as a hedge against the carbon risk while in the cited papers, their long-run risk comes directly from the aggregate consumption growth which is hardly detectable. This decomposition allows me to study the effects of climate change on macro-financial variables such as consumption growth, dividend growth, and the equity premium. My study is also related to the strand of literature on climate finance. Papers here include Daniel et al. (2016), Bansal et al. (2016b), Bansal et al. (2017), Chen et al. (2019), Giglio et al. (2021), Stroebe and Wurgler (2021), Avramov et al. (2021), etc. This paper is focused on the carbon or transition risk<sup>2</sup> while those papers study the physical risk<sup>3</sup> side of the climate risk. Especially, since climate change is a long horizon phenomenon, we need to assess it using a long-run risks model by looking at the consumption or households side.

---

<sup>2</sup> Risk inherent to the process of transitioning to a lower-carbon economy. For example, there are policy and legal risks, technology risk, market risk, and reputation risk

<sup>3</sup> Event driven risks which cause damage to assets and disrupt the supply chain (for example hurricanes, floods, fire.), and the long-term shifts in climate patterns ( for example increasing temperature or sea level rise)

The rest of the paper is organized as followed. In section 1, we describe the methodology to build a new measure of consumption-based carbon risk. Section 2 sets up the theoretical model. Section 3 presents the results and the asset pricing implication of the model, and section 4 concludes.

# 1 A measure of consumption-based carbon risk

The central challenge of climate finance is to capture the actual impact of carbon emissions. To deal with that, this paper uses aggregate consumption data and the carbon footprint to identify a carbon/green risk measure. All data are on annual basis and span the period 1930-2018. I describe below how I constructed the carbon consumption, green consumption measures to assess the empirical implication of a long-run carbon consumption risks model. Summary statistics are presented in table 1.

To construct the carbon consumption, I consider the carbon dioxide emissions from a household consumption perspective. The carbon dioxide emissions from a consumption perspective indicators provide an alternative view of carbon dioxide emissions, where the emissions are tied to the consumption of durable goods, non-durable goods and services in the United States. This allows accounting for a potential carbon leakage and the actual impact of carbon emissions in a given boundary. In fact, under the assumption of linear life cycle progression of product, households stand at the usage stage where they have control of the product. Using the NIPA <sup>4</sup> data, I collect aggregate information on 11 consumption categories (Food, clothing, housing, furniture, health, transportation, communication, recreation, education, food services and accommodation, financial services and insurance). Then, I match this aggregate information to the carbon footprint information provided by the Economic Input-Output Life Cycle Assessment (EIO-LCA) database using the purchaser (retail) price model<sup>5</sup>. The Life cycle assessment (LCA) investigates, estimates, and evaluates the environmental burdens caused by a material, product, process, or service throughout its life span. Environmental burdens include the materials and energy resources required to create

---

<sup>4</sup> National Income and Product Accounts. I use US households annual aggregate consumption data and span 1930-2018.

<sup>5</sup> A commodity-based model. The purchaser model is designed to adjust for retail to producer prices, and thus model the delivery and retailing stages of the supply chain, as well as allowing modeling of commodities as opposed to industrial activity (e.g., a car instead of ‘automobile production’).

the product, as well as the wastes and emissions generated during the process. The EIO-LCA is developed by Carnegie Mellon University ([Institute. \(2021\)](#)) and it provides an estimate of economy-wide cradle-to-gate GHG emissions per dollar of producer output for 428 sectors of the U.S. economy. This paper uses the US 2002 Benchmark model - purchaser price<sup>6</sup> to collect the carbon footprint for the 11 household expenditure categories identified in the NIPA data. I identify in the Economic Input-Output Life Cycle Assessment database a total of 50 sectors representing household consumption good productions. A sample of such carbon emissions is given in figure 2 for power generation and supply (electricity), and soft drink and ice manufacturing. It depicts the direct and indirect emissions due to the purchase of \$US 1 million of electricity for the left panel and soft drink for the right panel. It amounts to 9,370 and 651 tons of CO<sub>2</sub> emissions (t CO<sub>2</sub>e) respectively. We notice electricity has a higher burden on the environment than soft drinks.

Using these 50 sectors, we covered 96% of total household consumption expenditure which represents a total of 29 consumption goods out of 44 in the NIPA data table. In Figure 3, the x-axis captures the tons of CO<sub>2</sub> emissions (tCO<sub>2</sub>e) per million of US dollars. Figure 3 displays the total carbon footprint in each consumption category. As shown, transport, food, and housing account for a large part of the carbon footprint in household consumption expenditure representing a total of 77% of US household dioxide carbon emissions. In household consumption baskets, food and beverages contribute the most in carbon footprint followed by housing, household utilities, furnishings, recreation, and transportation.

The direct carbon dioxide emissions, which include natural gas, motor oil, and lubricant grass represent only 11% of the total emissions in the household's consumption basket. In this paper, we use both direct and indirect burdens to compute the total carbon emissions.

---

<sup>6</sup> The US 2002 model uses information on the 2002 US economy.

Figure 1: Fact

OurWorldInData.org/co2-and-other-greenhouse-gas-emissions • CC BY

Next, I map the NIPA expenditure category to the carbon footprint information to compute the consumption-based carbon. Since the carbon footprint information is related to the 2002 consumer price purchase, all the NIPA data are deflated using the 2002 reference base period for the consumer price index (CPI). Figure 2 shows that all the consumption categories do not affect equally the environment. Therefore, this paper weights the aggregate consumption of each good and service by its burden on the atmosphere to compute a new total consumption measure. The total US-household consumption-based carbon emissions can be expressed simply as the product of consumption, denoted  $C$ , in dollars, and carbon emissions per unit of consumption, denoted  $CE$ , summed over each carbon footprint activity ( $i$ ) included in the model. Put it simply, when it comes to analyzing the effect of carbon emissions on the economy, environment, consumption categories should not be treated as the same. Each category affects differently the environment, so I compute the aggregate consumption by weighting each category consumption by its footprint. Alternatively, I classify the carbon footprint in decreasing order and use the five categories with the highest carbon

Figure 3: Carbon footprint by household expenditure category.

Note: x-axis captures the tons of CO2 emissions (tCO2e) per million of US dollars

footprints to compute what I call carbon consumption and the leftover to compute the green consumption. Overall, the total carbon emissions at any time  $t$  are calculated as follow:

$$TC_t = \sum_{i=1}^{11} C_{i,t} * CE_i \quad (1)$$

However, I subdivide all the consumption categories into two parts to be able to separate the usual consumption risk into two risks. The first risk measures the carbon consumption risk - including the consumption categories which pollute the most based on their footprint, see equation 2). The second risk measures the green consumption risk - including the consumption categories which pollute the least based on their footprint, see equation 3). Henceforth, I will call the risk associated with the green consumption,

"green risk" and the risk associated to the carbon consumption, "carbon risk".

$$CC_t = \sum_{i=1}^5 C_{i,t} * CF_i \text{ or } \sum_{i=1}^5 C_{i,t} \quad (2)$$

$$GC_t = \sum_{i=6}^{11} C_{i,t} * CF_i \text{ or } \sum_{i=6}^{11} C_{i,t} \quad (3)$$

The pattern of those components is shown on the figure 1 in term of log difference:

$$\Delta cc_{t+1} = \log \left( \frac{CC_{t+1}}{CC_t} \right) \quad (4)$$

$$\Delta gc_{t+1} = \log \left( \frac{GC_{t+1}}{GC_t} \right) \quad (5)$$

$$\Delta \alpha_{cc,t+1} = \log \left( \frac{\alpha_{cc,t+1}}{\alpha_{cc,t}} \right) \quad (6)$$

where  $\alpha_{cc,t} = \frac{CC_t}{C_t}$ . I call  $\Delta cc_{t+1}$  carbon consumption growth risk,  $\Delta gc_{t+1}$  green consumption growth risk,  $\Delta \alpha_{cc,t}$  share of carbon consumption growth risk. I could have defined in the same manner the share of green consumption growth risk ( $\Delta \alpha_{gc,t}$ ).

Figure 4 displays the time series of the key variables of this paper. One can clearly see that the series replicate some business cycles and climate change events.

Figure 4: Carbon risk, green risk and Household expenditure growth

To link the real economy to the financial market, I also use data on industry, small, large, value, and growth portfolio returns from Kenneth R. French's website. I use value-weighted portfolios including and excluding dividends to compute the dividend and price series on the per-share basis (Campbell and Shiller (1988), Hansen et al. (2008)). Table 1 presents some descriptive statistics. All returns and dividend growth series have been deflated using the consumer price index growth.

Table 1: Summary statistics

$r_f$	0.0025	0.0351	0.6852	0.3059	0.2040	0.2336	0.2788

The table reports the sample mean, standard deviation, and first-order to fifth order autocorrelation of the marketwide log price/dividend ratio, the log dividend, consumption and (share of) carbon/green consumption growth rates.

## 2 Model

The model builds on [Bansal and Yaron \(2004\)](#) LRR model and uses insight from [Giglio et al. \(2021\)](#). My model introduces three state variables: a long-run risk variable, the variance of the innovation of the carbon consumption growth alongside with the growth rate of the share of carbon consumption out of total consumption that jointly drive the conditional mean of the aggregate consumption growth, and the dividends growth.

### 2.1 Preferences

In this economy, there is a representative household with recursive preferences ([Kreps and Porteus \(1978\)](#), [Epstein and Zin \(1989\)](#)). This paper chooses these types of preferences for two main reasons: First, they allow for separation between the coefficient of risk aversion and the elasticity of inter-temporal substitution. Second, an Epstein–Zin (EZ) investor’s marginal utility depends both on the one-period innovation in consumption growth rate and on news about consumption growth at future horizons. This is an important feature for the climate change thematic as the news about future global warming will affect consumers’ consumption behaviors. Hence, the consumption growth will incur a proportional shock. One would like a utility function specification that affects the level of the climate risk premium and the term structure of the discount rate. Epstein–Zin utility specified in equation 7 does what I just described.

$$V_t = \left[ (1 - \delta) C_t^{\frac{1-\gamma}{\theta}} + \delta (E_t[V_{t+1}]^{1-\gamma})^{\frac{1}{\theta}} \right]^{\frac{\theta}{1-\gamma}} \quad (7)$$

where  $\delta$  is the subjective discount factor parameter,  $\gamma > 0$  is the coefficient of risk aversion,  $\theta = \frac{1-\gamma}{1-\frac{1}{\psi}}$  with  $\psi > 0$  represents the elasticity of inter-temporal substitution (EIS). The standard time-separable power utility model is a special case for the EZ utility when  $\gamma = \frac{1}{\psi}$ . The agent prefers early resolution of the risk if  $\gamma > \frac{1}{\psi}$  and late

resolution if  $\gamma < \frac{1}{\psi}$ .

In this formulation, the household evaluates her consumption plan recursively. She consumes at time  $t$  and receives a continuation value of her consumption which can bear a long-run risk component through its carbon consumption. Indeed, with a canonical expected utility risk, only short-run risks are compensated, while long-run risks do not carry a separate risk premium. With the above preference, long-run risks earn a positive risk premium if households prefer early resolution of uncertainty.

Furthermore, there are  $N+1$  tradable assets in the economy: one risk-free asset ( $i = 0$ ) and  $N$  risky assets ( $i = 1, \dots, N$ ). In each period  $t$ , the representative household invests  $X_{it}$  unit of its discretionary wealth in asset  $i$ . The tradable asset  $i$  has a price of  $P_{it}$  and a future dividend of  $D_{it}$ , with a gross return of  $R_{it+1} = \frac{D_{it+1} + P_{it+1}}{P_{it}}$ . The inter-temporal budget constraint faced by the household is given by

$$C_t + \sum_{i=1}^{N+1} P_{it} X_{i,t+1} = \sum_{i=1}^{N+1} (P_{it} + D_{it}) X_{it} = W_t \quad (8)$$

where

$$C_t = CC_t + GC_t$$

is the total consumption and the sum of the consumption considered as carbon consumption ( $CC_t$ ) and the consumption considered as green consumption ( $GC_t$ ).

## 2.2 A long-run carbon consumption risks (LRCCR) model

This paper assumes that consumption growth in the economy depends on two components. One carries a long-run risk and the other does not carry any long-run risks. In particular, we assume that aggregate consumption growth is given by (the proof can be found in [appendix A](#)):

$$\Delta c_{t+1} = \underbrace{\Delta cc_{t+1}}_{\text{Carbon}} - \underbrace{\Delta \alpha_{cc,t+1}}_{\text{share of } cc} \quad (9)$$

where  $\Delta c_{t+1} = \log \left( \frac{C_{t+1}}{C_t} \right)$  is the log consumption growth rate.  $\Delta cc_{t+1}$  is the growth rate of the carbon consumption and  $\Delta \alpha_{cc,t+1}$  is the growth rate of the share of carbon consumption in the total consumption as defined in section 1 equations 4-6. Note that the conditional mean of  $cc_{t+1}$ , and its conditional volatility are a source of carbon consumption risk. In fact, transition to a low-carbon economy raises the future likelihood of carbon consumption risk, which if realized, leads to a consumption risk. For instance, the nationally determined contributions(NDC) policy scenario aims to reduce carbon consumption by 32(15) gigatons of CO2 to stay within the 1.5° C(2° C) by 2030. The dynamic of the other variables are described as follows:

$$\Delta cc_{t+1} = \nu_{cc} + x_t + \sigma_t \epsilon_{cc,t+1} \quad (10)$$

$$x_{t+1} = \rho_x x_t + \psi_x \sigma_t \epsilon_{x,t+1} \quad (11)$$

$$\sigma_{t+1}^2 = (1 - \nu) \sigma^2 + \nu \sigma_t^2 + \sigma_w \epsilon_{\sigma,t+1} \quad (12)$$

Thus, in our model  $x_t$ ,  $\Delta \alpha_{cc,t}$ , and  $\sigma_t^2$  are the state variables. In particular,  $x_t$  captures the conditional mean of the carbon consumption growth rate, while  $\sigma_t^2$  captures the uncertainty due to the transition to a lower-carbon economy. The growth of the share of carbon consumption out of total consumption component doesn't carry any long-run risk and evolves as given by

$$\Delta \alpha_{cc,t+1} = \nu_\alpha (1 - \rho_\alpha) + \rho_\alpha \Delta \alpha_{cc,t} + \sigma_\alpha \epsilon_{\alpha,t+1} + \pi \sigma_t \epsilon_{cc,t+1} \quad (13)$$

This paper assumes that the innovations of the share of carbon consumption out of total consumption, and the carbon consumption are correlated. That correlation depends on the parameters  $\pi$ <sup>7</sup> and  $\sigma_\alpha$ . Finally, the dividend growth rate of any dividend-paying asset  $i$  is as follows

$$\Delta d_{i,t+1} = \nu_i + \phi_i x_t + \phi_{\alpha,i} \Delta \alpha_{cc,t} + \psi_i \sigma_t \epsilon_{i,t+1} \quad (14)$$

---

<sup>7</sup> Alternative specification :  $\epsilon_{\alpha,t}$  and  $\epsilon_{cc,t}$  are correlated instead of iid and set  $\pi = 0$

Where  $\phi_i$ ,  $\phi_{\alpha,i}$ ,  $\psi_i$  determine asset  $i$ 's exposure to the long-run, share of carbon consumption and volatility risks, respectively. The shocks  $\epsilon_{x,t+1}$ ,  $\epsilon_{\alpha,t+1}$ ,  $\epsilon_{i,t+1}$ ,  $\epsilon_{cc,t+1}$  and  $\epsilon_{\sigma,t+1}$  are assumed to be i.i.d.  $N(0,1)$  and mutually independent. Equations (9)-(14) represent the building block of our long-run carbon consumption risks model, henceforth LRCCR model. The dynamic of the variables and the utility function involve seventeen parameters  $\Theta=[\rho_x \ \psi_x \ \psi_i \ \nu_{cc} \ \nu \ \nu_i \ \sigma_w \ \sigma \ \phi_i \ \delta \ \gamma \ \psi \ \nu_\alpha \ \rho_\alpha \ \sigma_\alpha \ \pi \ \phi_{\alpha,i}]$ . I calibrate the model parameters to match key sample moments. I derive some moments condition for the carbon consumption, the share of carbon consumption and asset  $i$  dividend growth rates as functions of the time-series and the preferences parameters. See the appendices section 4 for more details.

## 2.3 Solving the model

For any asset  $i$ , the corresponding Euler equation regarding from the consumer's utility maximization is given by:

$$\mathbb{E}_t[e^{m_{t+1}+r_{i,t+1}}] = 1 \quad (15)$$

where

$$m_{t+1} = \theta \log(\delta) - \frac{\theta}{\psi} \Delta c c_{t+1} + \frac{\theta}{\psi} \Delta \alpha_{cc,t+1} + (\theta - 1) r_{c,t+1} \quad (16)$$

is the natural logarithm of the stochastic discount factor;  $\mathbb{E}_t[\cdot]$  denotes expectation conditional on time  $t$  information;  $r_{i,t+1}$  is the continuously compounded return on asset  $i$ ; and  $r_{c,t+1}$  is the unobservable continuously compounded return on an asset that delivers aggregate consumption as its dividend each period.

Following [Campbell and Shiller \(1988\)](#), the log return on the consumption claim, namely  $r_{c,t+1}$ , and the log return of the asset  $i$   $r_{i,t+1}$  are approximated as follows :

$$r_{c,t+1} = \kappa_0 + \kappa_1 z_{t+1} - z_t + \Delta c c_{t+1} - \Delta \alpha_{cc,t+1} \quad (17)$$

$$r_{i,t+1} = \kappa_{0,i} + \kappa_{1,i}z_{i,t+1} - z_{i,t} + \Delta d_{i,t+1} \quad (18)$$

where  $z_t = \log\left(\frac{P_{m,t}}{C_t}\right)$  and  $P_{m,t}$  stands for the market portfolio price,  $z_{i,t} = \log\left(\frac{P_{i,t}}{D_{i,t}}\right)$ .  $\kappa_1 = \frac{e^{\bar{z}}}{1+e^{\bar{z}}}$  and  $\kappa_0 = \log(1+e^{\bar{z}}) - \kappa_1\bar{z}$  are log-linearization constants.  $\bar{z}$  denotes the long-run mean of the log price/consumption ratio ( $z$ ). Regarding equation (18),  $\kappa_{1,i} = \frac{e^{\bar{z}_i}}{1+e^{\bar{z}_i}}$  and  $\kappa_{0,i} = \log(1+e^{\bar{z}_i}) - \kappa_{1,i}\bar{z}_i$  where  $\bar{z}_i$  denotes the long-run mean of the log price/dividend ratio ( $z_i$ ). Whenever this paper uses a subscript  $m$ , it refers to the market portfolio and whenever, I use a subscript  $i$ , it refers to any asset.

As in [Bansal and Yaron \(2004\)](#), I conjecture that  $z_t$  and  $z_{i,t}$  are affine functions of the state variables  $x_t$  (LRR variable or conditional expected carbon consumption growth),  $\sigma_t^2$  (conditional volatility of the carbon consumption growth), and  $\Delta\alpha_{cc,t}$  (share of carbon consumption growth).

$$z_t = A_0 + A_1x_t + A_2\sigma_t^2 + A_3\Delta\alpha_{cc,t} \quad (19)$$

$$z_{i,t} = A_{0,i} + A_{1,i}x_t + A_{2,i}\sigma_t^2 + A_{3,i}\Delta\alpha_{cc,t} \quad (20)$$

$A_0$ ,  $A_1$ ,  $A_2$ ,  $A_3$ ,  $A_{0,i}$ ,  $A_{1,i}$ ,  $A_{2,i}$ , and  $A_{3,i}$  are function of parameters in  $\Theta$  and the linearization parameters. Their expressions are given in the Appendix. An increase in the expected carbon consumption growth rate will raise the price-consumption ratio if the intertemporal substitution effect dominates the wealth effect. However, a higher share of carbon consumption out of total consumption implies a lower price-consumption ratio when  $\psi > 1$ . Turning now into the price-dividend ratio, the conclusions are different for the share of carbon consumption growth effect. While the expected carbon consumption growth still raises the price dividend ratio but much higher under the conditions that  $\psi > 1$  and  $\phi_i > 1$  (the LRR variable acts as a leverage), the share of carbon consumption now positively affects the price-dividend ratio hypothesizing  $\phi_{\alpha,i} > 0$ .

Using equation 15, I show that the log-risk free rate can be written in function

of the carbon-consumption and its volatility (state variables) as follows:

$$\begin{aligned} r_{f,t} &= -\log \mathbb{E}_t[e^{m_{t+1}}] \\ &= A_{0,f} + A_{1,f}x_t + A_{2,f}\sigma_t^2 + A_{3,f}\Delta\alpha_{cc,t} \end{aligned} \quad (21)$$

Once again  $A_{0,f}$ ,  $A_{1,f}$ ,  $A_{2,f}$ ,  $A_{3,f}$  are function of parameters in  $\Theta$  and the linearization parameters and their expression are given in the Appendix.

## 2.4 Testable implications for Asset prices: $m_{t+1}$

To test the implication of the model for equity premium and the cross-section of returns, I combine equations (16), (17), (19) to get the expression of the stochastic discount factor in terms of state variables:

$$\begin{aligned} m_{t+1} &= (\theta \log(\delta) + (\theta - 1)[\kappa_0 + (\kappa_1 - 1)A_0]) + \left(-\frac{\theta}{\psi} + (\theta - 1)\right) \Delta cc_{t+1} \\ &\quad + \left(\frac{\theta}{\psi} - (\theta - 1) + (\theta - 1)\kappa_1 A_3\right) \Delta\alpha_{cc,t+1} \\ &\quad + (\theta - 1)\kappa_1 A_1 x_{t+1} + (\theta - 1)\kappa_1 A_2 \sigma_{t+1}^2 \\ &\quad - (\theta - 1)A_1 x_t - (\theta - 1)A_2 \sigma_t^2 - (\theta - 1)A_3 \Delta\alpha_{cc,t} \end{aligned} \quad (22)$$

The innovation in the  $m_{t+1}$  conditional on time- $t$  information is given by:

$$m_{t+1} - \mathbb{E}_t[m_{t+1}] = -\lambda_{m,\alpha}\sigma_\alpha\epsilon_{\alpha,t+1} - \lambda_{m,cc}\sigma_t\epsilon_{cc,t+1} - \lambda_{m,x}\sigma_t\epsilon_{x,t+1} - \lambda_{m,w}\sigma_w\epsilon_{\sigma,t+1} \quad (23)$$

Therefore, the equity risk premium for any asset  $i$  is :

$$\mathbb{E}_t(r_{i,t+1} - r_{f,t}) + 0.5\mathbb{V}_t(r_{i,t+1}) = \lambda_{m,x}\beta_{i,x}\sigma_t^2 + \lambda_{m,w}\beta_{i,w}\sigma_w^2 + \lambda_{m,\alpha}\beta_{i,\alpha}\sigma_\alpha^2 + \lambda_{m,cc}\beta_{i,cc}\sigma_t^2 \quad (24)$$

where the  $\beta$ 's are the asset  $i$  exposures to the long-run risk, the volatility risk, the share of carbon consumption risk, and the short-run risk, and the  $\lambda$ 's are the respective risk prices.  $\beta$ 's and  $\lambda$ 's are functions of the preference parameters, the linearization

parameters, and the dynamics of macro-financial variables dynamic parameters (see appendix 4). The price of the short-run carbon consumption risk and the exposure of any asset on this risk rise with the correlation between the share of carbon growth and the carbon growth.  $\lambda_{m,x}$ , and  $\beta_{i,x}$  increase with the persistence of the expected carbon growth. In the same way,  $\lambda_{m,cc}$ ,  $\lambda_{m,\alpha}$ ,  $\beta_{i,cc}$ , and  $\beta_{i,\alpha}$  increase with the persistence of the share of carbon consumption out of total consumption growth.

I substitute equation (22) into the set of Euler equations (15) to have moment conditions that are expressed entirely in terms of observables. Then I examine the empirical plausibility of the model when the set of assets in the economy consists of the market portfolio and the risk-free rate, thereby focusing on the equity premium and risk-free rate puzzles. In particular, I consider a set of moments, namely the expected value and the standard deviation of the equity premium, the real risk-free rate, and the price-dividend ratio, and I calibrate the parameters  $\Theta$  to match those moments. Next, this paper examines whether the model can explain the cross-section of returns in different asset classes including “carbon-intensive” (high heat-exposed and low heat-exposed) portfolios and Fama-French twenty-five portfolios. In total, I use the 42 Fama-French industry portfolios and 25 FFPs.

## 2.5 Cross-sectional implication of the LRCCR model

This paper decomposes the consumption growth risk  $\Delta c_t$  into two new risks. Namely, the carbon consumption (cc) growth risk ( $\Delta cc_t$ ) and the share of carbon consumption (shcc) growth risk ( $\Delta \alpha_{cc,t}$ ). I adopt Fama and MacBeth (1973) two-pass regression methodology to estimate the risk premia on each risk factor (see also Kan et al. (2013), Bai and Zhou (2015)). In the first stage, I compute the portfolio’s exposures to the risk factors by regressing each portfolio excess return ( $r_{i,t}$ ) on  $\Delta cc_t$  and  $\Delta \alpha_t$ :

$$r_{i,t} = c_i + \beta_{sh,i} \Delta \alpha_{cc,t} + \beta_{cc,i} \Delta cc_t + \epsilon_{i,t} \quad i = 1, \dots, N \quad (25)$$

In the second stage, I run a cross-sectional regression of  $r_{i,t}$  on the betas from the first stage time-series regression for each period  $t$  (see equation 27).

$$r_{i,t} = a_t + \gamma_{sh,t}\hat{\beta}_{sh,i} + \gamma_{cc,t}\hat{\beta}_{cc,i} + \epsilon_{i,t} \quad t = 1, \dots, T \quad (26)$$

Rather than running  $T$  cross-sectional regression (CSR), I run a single CSR of the sample excess return mean  $\mu_r$  a constant and the betas estimated from the first stage. Put in equation terms, it gives:

$$\mu_{r,i} = \gamma_0 + \gamma_{sh}\hat{\beta}_{sh,i} + \gamma_{cc}\hat{\beta}_{cc,i} + \epsilon_i \quad i = 1, \dots, N \quad (27)$$

For comparison purposes, this paper applies also the two-pass regression to the case of one consumption growth risk factor. I plot the exposures  $\beta_{sh,i}$ 's and  $\beta_{cc,i}$ 's in Figure 6. Once we know which portfolio (industry) is significantly positively and negatively exposed to the carbon risk, I calibrate the LRCCR model to match key moments of those portfolios (industries). The main goal is to explain the cross-section of the portfolios (industries) expected returns. My parameters of interest are the leverage parameters, i.e the dividend exposures to the long-run risk variable and to the share of carbon consumption growth rate for each portfolio (industry)  $\phi_i$ , and  $\phi_{\alpha,i}$  and the dividend exposure to volatility risks  $\psi_i$ . To test the effectiveness of the LRCCR model, I start by looking at the cross-sectional properties of the well-known portfolios. Especially, the value, growth, small size, and large portfolios. Based on empirical evidence (see Bansal et al. (2005) and Hansen et al. (2008), Bansal et al. (2016a)), the value portfolio presents a much higher exposure to low-frequency risks in consumption relative to the growth portfolio. Likewise, the long-run risk exposure of the small-size portfolio exceeds that of the large-size portfolio. Next, I look at the cross-sectional properties of the Fama-French industry portfolios.

### 3 Model estimation

#### 3.1 Equity premium, volatility and risk-free rate: BY2004 versus LRCCR

In this part, this paper compares the LRCCR and LRR models in terms of replicating the observed equity premium, volatility of the equity premium, and the risk-free rate. This paper calibrates the seventeen parameters  $\Theta = [\rho_x \ \psi_x \ \psi_d \ \nu_{cc} \ \nu \ \nu_d \ \sigma_w \ \sigma \ \phi_d \ \delta \ \gamma \ \psi \ \nu_\alpha \ \rho_\alpha \ \sigma_\alpha \ \pi \ \phi_{\alpha,d}]$  to match (share of) carbon consumption growth, (share of) green consumption growth, dividend growth, market return and risk-free rate means, variances, (auto)correlations observed in the data. The calibration results are displayed in table 2 for both my setting and Bansal and Yaron (2004)'s setting. I present four sets of results: full sample, the period around World War II, the period around the First Earth Day and finally post Reagan Election sample. This paper does this split because returns react to news and back in the days, climate change or global warming was not a big issue. Therefore, we hypothesize that there is probably no big effect during the pre-Reagan Election period using the President Reagan Election as reference day because global public awareness of energy conservation and improvements in energy efficiency start around this period.

$\Psi_x$  tells us how detectable the long-run variable is. The results show that the long-run risk variable is more detectable than BY during the 1956-2018 near climate change events period. From results in the table 2, there are long-run risks in the volatility and the carbon consumption growth:  $\nu$  smaller and close to one; and  $\rho_x$  smaller and close to one. Overall, the risk aversion in our model is higher than the one in Bansal and Yaron (2004)'s setting but is in a reasonable range. This high value is due to the nature of the risk I am talking about (carbon risk). Furthermore, agents fear more carbon risk than consumption risk because the carbon risk will increase even more (amplify) the consumption risk.  $\phi_{\alpha,d}$  functions as a leverage ratio on the share of

carbon consumption growth during the period 1981-2018.

Table 2: Calibrated parameters

	1930-2018		1930-1955		1956-1980		1981-2018

$\phi_a$		0.590		0.877		-0.294		1.305

The table reports the calibrated parameters for the different sub-samples for both our setting (LRCCR) and [Bansal and Yaron \(2004\)](#) setting (BY04).

This paper simulates the time series of the model-implied carbon consumption growth, the share of carbon consumption growth, dividend growth, market return, and risk-free rate and I present some quantiles of those series in tables 3 and 8 for the four samples. The quantiles 5% and 95% serve as the confident interval and the sample moments are overall within those intervals generated by our simulation in the preferred sub-samples.

Table 3: Model-implied moments.

		$\sigma(z_m)$	$EP$	$E(R_f)$	$\sigma(r_{m,a})$	$\sigma(r_{f,a})$	$\rho(z_m)$

	95%	0.330	0.178	0.027	0.220	0.009	0.946

The table reports the model-implied moments (the equity premium (EP), the mean of the risk free rate, the standard deviations of the log price-dividend ratio, the market return, and the risk-free rate, and the first-order autocorrelation of the log price-dividend ratio.) alongside with some 20-quantiles.

Now let us turn into the predictability implication of my model versus the one of [Bansal and Yaron \(2004\)](#) by comparing the predicted equity premium, consumption growth, and dividend growth rates and their realized counterparts. Most of the consumption capital asset pricing models find a constant risk premium: approximately constant predicted risk premium. However, during a period of high carbon emissions risk 1980-2018, a long-run carbon consumption risks model finds a time-varying risk premium. My model is much better than the usual Long-run risk model. (See Figures 5, and 7 in the Appendix). The difference is quite clear when I predict the macro-financial variables in the sub-sample, especially during the period 1981-2018, a period starting around the election of the United States President Reagan where climate actions started rising.

### **3.2 Risks and Price of risks**

In this section, I compute the price of the four risk sources this paper talked about in the model section: carbon consumption growth risk, the share of carbon consumption growth risk - which is correlated to the share of green consumption growth risk-, long-run risk and the volatility risk. The most important result from table 4, is the consistent sign of the contribution of the volatility risk in the equity premium under my model. The market is negatively exposed to the volatility risk in every sample I considered.

Figure 5: **Realized versus predicted equity premium, consumption growth and dividend growth.** In this figure,

### 3.3 Cross-sectional implication

As one can see from figure 6, I cannot classify the industries based on their betas until 1955. All industries are positively and negatively exposed to carbon consumption growth risk and share of carbon consumption growth risk respectively. Except for the Rubber and Plastic Products industry, which is negatively and positively exposed to carbon consumption growth risk and share of carbon consumption growth risk respectively. As of 1956, the risk factors start to affect differently the industries. This is really interesting as result. Because, it tells us that our risk factors become able to identify industries that pollute the most based on their risk exposures when it matters the most.

Figure 6: Industries exposures to carbon consumption risks :  $\beta$ 's

## 4 Conclusion

This article tackles the long-run carbon consumption risks model by allowing both long-run risks in mean and in volatility. We use Epstein-Zin utility function to disentangle the risk aversion coefficient and because of its property to deal with climate change thematic. This paper found empirical support to the long-run risks model in the context of carbon-green consumption. We have three state variables that define completely the other variables in the economy. To sum up, our long-run carbon consumption model solves the equity premium, volatility, and risk-free rate puzzles by decomposing the consumption growth into two components-the growth rate of carbon consumption component and the growth rate of the share of green consumption out of total consumption. Our model setting increases the ability of the investors to detect the long-run risk. Namely, investors can profit from it by using climate change news. Also, our long-run risk variable explains the cross-section of industries/firms. Thus, this paper recommends using the carbon risk measures we computed to identify industries or firms which pollute the most and construct an investment strategy that minimizes/maximizes a long-term environmental criterion.

Further research can use other proxies for the green component in the consumption decomposition and do the same analysis. Such proxy could be R&D expenses of carbon-intensive firms allocated to green technology or the revenue from selling the Solar Renewable Energy Certificates (SRECs).

# Appendices

## A Consumption growth decomposition

Let us consider  $I$  categories of consumption among which  $J$  carbon consumption categories and  $I - J$  green consumption categories.

$$C_t = \sum_{i=1}^I C_{i,t} \quad (28)$$

$$C_t = \sum_{i=1}^J C_{i,t} + \sum_{i=J+1}^I C_{i,t} \quad (29)$$

$$C_t = CC_t + GC_t \quad (30)$$

Growth rate decomposition :

$$\Delta c_{t+1} = \log(CC_{t+1} + GC_{t+1}) - \log(CC_t + GC_t) \quad (31)$$

$$\Delta c_{t+1} = \log(CC_{t+1}) + \log \frac{CC_{t+1} + GC_{t+1}}{CC_{t+1}} - \log(CC_t) - \log \frac{CC_t + GC_t}{CC_t} \quad (32)$$

$$\Delta c_{t+1} = \Delta cc_{t+1} - \left( \log \frac{CC_{t+1}}{CC_{t+1} + GC_{t+1}} - \log \frac{CC_t}{CC_t + GC_t} \right) \quad (33)$$

$$\Delta c_{t+1} = \Delta cc_{t+1} - \Delta \alpha_{CC,t+1} \quad (34)$$

where  $\Delta c_{t+1}$ ,  $\Delta cc_{t+1}$  and  $\Delta \alpha_{CC,t+1}$  are consumption, carbon consumption and carbon consumption share growth rates (log-difference) respectively.

## B Price of risks

$$\lambda_{m,\alpha} = (-\gamma + (1 - \theta)\kappa_1 A_3) \quad (35)$$

$$\lambda_{m,cc} = \gamma + (-\gamma + (1 - \theta)\kappa_1 A_3) \pi \quad (36)$$

$$\lambda_{m,x} = (1 - \theta)\kappa_1 A_1 \psi_x \quad (37)$$

$$\lambda_{m,w} = (1 - \theta)\kappa_1 A_2 \quad (38)$$

are prices of risk that correspond to the four sources of risk  $\epsilon_{\alpha,t+1}$ ,  $\epsilon_{cc,t+1}$ ,  $\epsilon_{x,t+1}$ ,  $\epsilon_{\sigma,t+1}$ .

## C Theoretical moments calculation

From the carbon/green consumption growth rate processes, we have :

$$\mathbb{E}[\Delta cc_{t+1}] = \nu_{cc} \quad (39)$$

$$\mathbb{E}[\Delta \alpha_{cc,t+1}] = \nu_{\alpha} \quad (40)$$

$$\begin{aligned} \mathbb{V}[\Delta cc_{t+1}] &= \mathbb{V}[\nu_{cc} + x_t + \sigma_t \epsilon_{cc,t+1}] \\ &= \mathbb{V}[x_t] + \mathbb{V}[\sigma_t \epsilon_{cc,t+1}] \\ &= \frac{\psi_x^2}{1 - \rho_x^2} \sigma^2 + \sigma^2 \end{aligned} \quad (41)$$

$$\begin{aligned} \mathbb{V}[\Delta \alpha_{cc,t+1}] &= \mathbb{V}[\nu_{\alpha}(1 - \rho_{\alpha}) + \rho_{\alpha} \Delta \alpha_{cc,t} + \sigma_{\alpha} \epsilon_{\alpha,t+1} + \pi \sigma_t \epsilon_{cc,t+1}] \\ (1 - \rho_{\alpha}^2) \mathbb{V}[\Delta \alpha_{cc,t+1}] &= \sigma_{\alpha}^2 + \pi^2 \sigma^2 \\ \mathbb{V}[\Delta \alpha_{cc,t+1}] &= \frac{\sigma_{\alpha}^2 + \pi^2 \sigma^2}{1 - \rho_{\alpha}^2} \end{aligned} \quad (42)$$

$$Cov[\Delta cc_{t+1}, \Delta cc_{t+2}] = \rho_x \frac{\psi_x^2}{1 - \rho_x^2} \sigma^2 \quad (43)$$

$$\begin{aligned} Cov[\Delta \alpha_{cc,t+1}, \Delta \alpha_{cc,t+2}] &= Cov[\Delta \alpha_{cc,t+1}, \rho_\alpha \Delta \alpha_{cc,t+1} + \sigma_\alpha \epsilon_{\alpha,t+2} + \pi \sigma_{t+1} \epsilon_{cc,t+2}] \\ &= \rho_\alpha \mathbb{V}[\Delta \alpha_{cc,t+1}] \\ &= \rho_\alpha \frac{\sigma_\alpha^2 + \pi^2 \sigma^2}{1 - \rho_\alpha^2} \end{aligned} \quad (44)$$

From the dividend growth rate process, we can get :

$$\mathbb{E}[\Delta d_{t+1}] = \nu_i + \phi_{\alpha,i} \nu_\alpha \quad (45)$$

$$\begin{aligned} \mathbb{V}[\Delta d_{i,t+1}] &= \phi_i^2 \mathbb{V}[x_t] + \phi_{\alpha,i}^2 \mathbb{V}[\Delta \alpha_{cc,t}] + \psi_i^2 \mathbb{V}[\sigma_t \epsilon_{i,t+1}] \\ &= \phi_i^2 \frac{\psi_x^2}{1 - \rho_x^2} \sigma^2 + \phi_{\alpha,i}^2 \frac{\sigma_\alpha^2 + \pi^2 \sigma^2}{1 - \rho_\alpha^2} + \psi_i^2 \sigma^2 \end{aligned} \quad (46)$$

$$\begin{aligned} Cov[\Delta d_{i,t+1}, \Delta d_{i,t+2}] &= Cov[\phi_i x_t + \phi_{\alpha,i} \Delta \alpha_{cc,t} + \psi_i \sigma_t \epsilon_{i,t+1}, \phi_i x_{t+1} + \phi_{\alpha,i} \Delta \alpha_{cc,t+1} + \psi_i \sigma_{t+1} \epsilon_{i,t+2}] \\ &= \phi_i^2 Cov[x_t, x_{t+1}] + \phi_{\alpha,i}^2 Cov[\Delta \alpha_{cc,t}, \Delta \alpha_{cc,t+1}] \\ &= \phi_i^2 \rho_x \mathbb{V}[x_t] + \phi_{\alpha,i}^2 \rho_\alpha \frac{\sigma_\alpha^2 + \pi^2 \sigma^2}{1 - \rho_\alpha^2} \\ &= \phi_i^2 \rho_x \frac{\psi_x^2}{1 - \rho_x^2} \sigma^2 + \phi_{\alpha,i}^2 \rho_\alpha \frac{\sigma_\alpha^2 + \pi^2 \sigma^2}{1 - \rho_\alpha^2} \end{aligned} \quad (47)$$

From both carbon/green consumption and dividend growth rates, we get the cross moments :

$$\begin{aligned}
Cov[\Delta\alpha_{cc,t+1}, \Delta cc_{t+1}] &= Cov[\rho_\alpha \Delta\alpha_{cc,t} + \sigma_\alpha \epsilon_{\alpha,t+1} + \pi \sigma_t \epsilon_{cc,t+1}, x_t + \sigma_t \epsilon_{cc,t+1}] \\
&= \pi \mathbb{V}[\sigma_t \epsilon_{cc,t+1}] \\
&= \pi \sigma^2
\end{aligned} \tag{48}$$

$$\begin{aligned}
Cov[\Delta d_{i,t+1}, \Delta cc_{t+1}] &= Cov[\phi_i x_t + \phi_{\alpha,i} \Delta\alpha_{cc,t} + \psi_i \sigma_t \epsilon_{i,t+1}, x_t + \sigma_t \epsilon_{cc,t+1}] \\
&= \phi_i \mathbb{V}[x_t] \\
&= \phi_i \frac{\psi_x^2}{1 - \rho_x^2} \sigma^2
\end{aligned} \tag{49}$$

$$\begin{aligned}
Cov[\Delta d_{i,t+1}, \Delta\alpha_{cc,t+1}] &= Cov[\phi_i x_t + \phi_{\alpha,i} \Delta\alpha_{cc,t} + \psi_i \sigma_t \epsilon_{i,t+1}, \rho_\alpha \Delta\alpha_{cc,t} + \sigma_\alpha \epsilon_{\alpha,t+1} + \pi \sigma_t \epsilon_{cc,t+1}] \\
&= \phi_{\alpha,i} \rho_\alpha \mathbb{V}[\Delta\alpha_{cc,t}] \\
&= \phi_{\alpha,i} \rho_\alpha \frac{\sigma_\alpha^2 + \pi^2 \sigma^2}{1 - \rho_\alpha^2}
\end{aligned} \tag{50}$$

From the log price dividend process:

$$\mathbb{E}[z_{i,t}] = A_{0,i} + A_{2,i} \sigma^2 + A_{3,i} \nu_\alpha \tag{51}$$

$$\mathbb{V}[z_{i,t}] = A_{1,i}^2 \frac{\psi_x^2}{1 - \rho_x^2} \sigma^2 + A_{2,i}^2 \frac{\sigma_w^2}{1 - \nu^2} + A_{3,i}^2 \frac{\sigma_\alpha^2 + \pi^2 \sigma^2}{1 - \rho_\alpha^2} \tag{52}$$

$$\begin{aligned}
Cov[\Delta d_{i,t+1}, z_{i,t}] &= Cov[\phi_i x_t + \phi_{\alpha,i} \Delta\alpha_{cc,t} + \psi_i \sigma_t \epsilon_{i,t+1}, A_{1,i} x_t + A_{2,i} \sigma_t^2 + A_{3,i} \Delta\alpha_{cc,t}] \\
&= \phi_i A_{1,i} \frac{\psi_x^2}{1 - \rho_x^2} \sigma^2 + \phi_{\alpha,i} A_{3,i} \frac{\sigma_\alpha^2 + \pi^2 \sigma^2}{1 - \rho_\alpha^2}
\end{aligned} \tag{53}$$

$$\begin{aligned}
Cov[\Delta c_{t+1}, z_{i,t}] &= Cov[\Delta cc_{t+1} - \Delta \alpha_{cc,t+1}, A_{1,i}x_t + A_{2,i}\sigma_t^2 + A_{3,i}\Delta \alpha_{cc,t}] \\
&= Cov[x_t + \sigma_t \epsilon_{cc,t+1}, A_{1,i}x_t + A_{2,i}\sigma_t^2 + A_{3,i}\Delta \alpha_{cc,t}] \\
&\quad - Cov[\rho_\alpha \Delta \alpha_{cc,t} + \sigma_\alpha \epsilon_{\alpha,t+1} + \pi \sigma_t \epsilon_{cc,t+1}, A_{1,i}x_t + A_{2,i}\sigma_t^2 + A_{3,i}\Delta \alpha_{cc,t}] \\
&= A_{1,i} \frac{\psi_x^2}{1 - \rho_x^2} \sigma^2 - \rho_\alpha A_{3,i} \frac{\sigma_\alpha^2 + \pi^2 \sigma^2}{1 - \rho_\alpha^2} \quad (54)
\end{aligned}$$

**Return on consumption claim  $r_{c,t+1}$ , on dividend paying asset**

**$r_{i,t+1}$  and risk-free rate  $r_{f,t}$**

Let us determine  $z_t = A_0 + A_1x_t + A_2\sigma_t^2 + A_3\Delta \alpha_{cc,t}$ . From the Euler equation [15](#), we have :

$$\begin{aligned}
1 &= \mathbb{E}_t e^{\theta \log \delta - \frac{\theta}{\psi} \Delta c_{t+1} + \theta r_{c,t+1}} \\
&= e^{\mathbb{E}_t(\theta \log \delta - \frac{\theta}{\psi} \Delta c_{t+1} + \theta r_{c,t+1}) + 0.5 \mathbb{V}_t(\theta \log \delta - \frac{\theta}{\psi} \Delta c_{t+1} + \theta r_{c,t+1})} \\
&= e^{\theta \log \delta - \frac{\theta}{\psi} \mathbb{E}_t(\Delta c_{t+1}) + \theta \mathbb{E}_t r_{c,t+1} + 0.5 \mathbb{V}_t((-\frac{\theta}{\psi} + \theta) \Delta c_{t+1} + \theta \kappa_1 z_{t+1})} \\
&= \exp(\theta \log \delta + (1 - \gamma)(\nu_{cc} + x_t - \nu_\alpha(1 - \rho_\alpha) - \rho_\alpha \Delta \alpha_{cc,t}) + \theta(\kappa_0 - A_0 - A_1x_t - A_2\sigma_t^2 - A_3\Delta \alpha_{cc,t}) \\
&\quad + \theta \kappa_1(A_0 + A_1\rho_x x_t + A_2((1 - \nu)\sigma^2 + \nu\sigma_t^2) + A_3(\nu_\alpha(1 - \rho_\alpha) + \rho_\alpha \Delta \alpha_{cc,t})) \\
&\quad + 0.5 \{((1 - \gamma + \pi(-1 + \gamma + \theta \kappa_1 A_3))^2 + (\theta \kappa_1 A_1)^2 \psi_x^2) \sigma_t^2 + (-1 + \gamma + \theta \kappa_1 A_3)^2 \sigma_\alpha^2 + \theta^2 \kappa_1^2 A_2^2 \sigma_w^2\}) \\
0 &= \theta \log \delta + (1 - \gamma)(\nu_{cc} - \nu_\alpha(1 - \rho_\alpha)) + \theta(\kappa_0 - A_0) + \theta \kappa_1(A_0 + A_2(1 - \nu)\sigma^2 + A_3\nu_\alpha(1 - \rho_\alpha)) \\
&\quad + 0.5 \{(-1 + \gamma + \theta \kappa_1 A_3)^2 \sigma_\alpha^2 + \theta^2 \kappa_1^2 A_2^2 \sigma_w^2\} \\
&\quad + (1 - \gamma - \theta A_1 + \theta \kappa_1 A_1 \rho_x) x_t \\
&\quad + (-\theta A_2 + \theta \kappa_1 A_2 \nu + 0.5(1 - \gamma + \pi(-1 + \gamma + \theta \kappa_1 A_3))^2 + 0.5(\theta \kappa_1 A_1)^2 \psi_x^2) \sigma_t^2 \\
&\quad + (-(1 - \gamma)\rho_\alpha - \theta A_3 + \theta \kappa_1 A_3 \rho_\alpha) \Delta \alpha_{cc,t}
\end{aligned}$$

By identification :

$$\begin{aligned}
A_1 &= \frac{1 - \frac{1}{\psi}}{1 - \kappa_1 \rho_x} \\
A_3 &= -\frac{\left(1 - \frac{1}{\psi}\right) \rho_\alpha}{1 - \kappa_1 \rho_\alpha} \\
A_2 &= 0.5\theta \frac{\left(1 - \frac{1}{\psi} + \pi\left(-1 + \frac{1}{\psi} + \kappa_1 A_3\right)\right)^2 + (\kappa_1 A_1)^2 \psi_x^2}{1 - \kappa_1 \nu} \\
A_0 &= \frac{\log \delta + \left(1 - \frac{1}{\psi}\right)(\nu_{cc} - \nu_\alpha(1 - \rho_\alpha)) + \kappa_0 + \kappa_1(A_2(1 - \nu)\sigma^2 + A_3\nu_\alpha(1 - \rho_\alpha))}{1 - \kappa_1} \\
&+ \frac{0.5\theta \left\{ \left(-1 + \frac{1}{\psi} + \kappa_1 A_3\right)^2 \sigma_\alpha^2 + \kappa_1^2 A_2^2 \sigma_w^2 \right\}}{1 - \kappa_1}
\end{aligned}$$

Let us determine :

$$z_{i,t} = A_{0,i} + A_{1,i}x_t + A_{2,i}\sigma_t^2 + A_{3,i}\Delta\alpha_{cc,t}$$

Let us remind that one can rewrite the return on any asset and its dividend growth process as follow :

$$\begin{aligned}
r_{i,t+1} &= \kappa_{0,i} + \kappa_{1,i}z_{i,t+1} - z_{i,t} + \Delta d_{i,t} \\
\Delta d_{i,t+1} &= \nu_i + \phi_i x_t + \phi_{\alpha,i} \Delta\alpha_{cc,t} + \psi_i \sigma_t \epsilon_{i,t+1}
\end{aligned}$$

From the Euler equation [15](#), we have :

$$\begin{aligned}
1 &= \mathbb{E}_t e^{\frac{\theta}{\psi} \Delta c_{t+1} + (\theta-1)r_{c,t+1} + r_{i,t+1}} \\
&= e^{\frac{\mathbb{E}_t(\theta \log \delta - \frac{\theta}{\psi} \Delta c_{t+1} + (\theta-1)r_{c,t+1} + r_{i,t+1}) + 0.5 \mathbb{V}_t(\theta \log \delta - \frac{\theta}{\psi} \Delta c_{t+1} + (\theta-1)r_{c,t+1} + r_{i,t+1})}{\psi}} \\
&= e^{\frac{\theta \log \delta - \frac{\theta}{\psi} \mathbb{E}_t(\Delta c_{t+1}) + (\theta-1)\mathbb{E}_t r_{c,t+1} + \mathbb{E}_t r_{i,t+1} + 0.5 \mathbb{V}_t((-\frac{\theta}{\psi} \Delta c_{t+1} + (\theta-1)r_{c,t+1} + r_{i,t+1}))}{\psi}} \\
0 &= \theta \log \delta - \gamma(\nu_{cc} + x_t - \nu_\alpha(1 - \rho_\alpha) - \rho_\alpha \Delta \alpha_{cc,t}) + (\theta - 1)(\kappa_0 - A_0 - A_1 x_t - A_2 \sigma_t^2 - A_3 \Delta \alpha_{cc,t}) \\
&\quad + (\theta - 1)\kappa_1(A_0 + A_1 \rho_x x_t + A_2((1 - \nu)\sigma^2 + \nu\sigma_t^2) + A_3(\nu_\alpha(1 - \rho_\alpha) + \rho_\alpha \Delta \alpha_{cc,t})) + \kappa_{0,i} \\
&\quad + \kappa_{1,i}(A_{0,i} + A_{1,i} \rho_x x_t + A_{2,i}((1 - \nu)\sigma^2 + \nu\sigma_t^2) + A_{3,i}(\nu_\alpha(1 - \rho_\alpha) + \rho_\alpha \Delta \alpha_{cc,t})) + \nu_i + \phi_i x_t + \phi_{\alpha,i} \Delta \alpha_{cc,t} \\
&\quad + 0.5 \{(-\gamma + \pi(\gamma + (\theta - 1)\kappa_1 A_3 + \kappa_{1,i} A_{3,i}))^2 + ((\theta - 1)\kappa_1 A_1 + \kappa_{1,i} A_{1,i})^2 \psi_x^2 + \psi_i^2\} \sigma_t^2 \\
&\quad + 0.5(\gamma + (\theta - 1)\kappa_1 A_3 + \kappa_{1,i} A_{3,i})^2 \sigma_\alpha^2 \\
&\quad + 0.5((\theta - 1)\kappa_1 A_2 + \kappa_{1,i} A_{2,i})^2 \sigma_w^2 - A_{0,i} - A_{1,i} x_t - A_{2,i} \sigma_t^2 - A_{3,i} \Delta \alpha_{cc,t} \\
0 &= \theta \log \delta - \gamma(\nu_{cc} - \nu_\alpha(1 - \rho_\alpha)) + (\theta - 1)(\kappa_0 - A_0) + (\theta - 1)\kappa_1(A_0 + A_2(1 - \nu)\sigma^2 + A_3 \nu_\alpha(1 - \rho_\alpha)) + \kappa_{0,i} \\
&\quad + \kappa_{1,i}(A_{0,i} + A_{2,i}(1 - \nu)\sigma^2 + A_{3,i} \nu_\alpha(1 - \rho_\alpha)) + \nu_i \\
&\quad + 0.5(\gamma + (\theta - 1)\kappa_1 A_3 + \kappa_{1,i} A_{3,i})^2 \sigma_\alpha^2 + 0.5((\theta - 1)\kappa_1 A_2 + \kappa_{1,i} A_{2,i})^2 \sigma_w^2 - A_{0,i} \\
&\quad + (-\gamma - (\theta - 1)A_1 + (\theta - 1)\kappa_1 A_1 \rho_x + \kappa_{1,i} A_{1,i} \rho_x + \phi_i - A_{1,i}) x_t \\
&\quad + (0.5((-\gamma + \pi(\gamma + (\theta - 1)\kappa_1 A_3 + \kappa_{1,i} A_{3,i}))^2 + ((\theta - 1)\kappa_1 A_1 + \kappa_{1,i} A_{1,i})^2 \psi_x^2 + \psi_i^2)) \sigma_t^2 \\
&\quad + (-(\theta - 1)A_2 + (\theta - 1)\kappa_1 A_2 \nu + \kappa_{1,i} A_{2,i} \nu - A_{2,i}) \sigma_t^2 \\
&\quad + (\gamma \rho_\alpha - (\theta - 1)A_3 + (\theta - 1)\kappa_1 A_3 \rho_\alpha + \kappa_{1,i} A_{3,i} \rho_\alpha + \phi_{\alpha,i} - A_{3,i}) \Delta \alpha_{cc,t}
\end{aligned}$$

By identification :

$$\begin{aligned}
A_{1,i} &= \frac{\phi_i - \frac{1}{\psi}}{1 - \kappa_{1,i}\rho_x} \\
A_{3,i} &= \frac{\phi_{\alpha,i} + \frac{\rho_\alpha}{\psi}}{1 - \kappa_{1,i}\rho_\alpha} \\
A_{2,i} &= \frac{(1 - \theta)A_2(1 - \kappa_1\nu) + 0.5 \left\{ (-\gamma + \pi(\gamma + (\theta - 1)\kappa_1 A_3 + \kappa_{1,i} A_{3,i}))^2 + ((\theta - 1)\kappa_1 A_1 + \kappa_{1,i} A_{1,i})^2 \psi_x^2 + \psi_i^2 \right\}}{1 - \kappa_{1,i}\nu} \\
A_{0,i} &= \frac{\theta \log \delta - \gamma(\nu_{cc} - \nu_\alpha(1 - \rho_\alpha)) + (\theta - 1)(\kappa_0 - A_0) + (\theta - 1)\kappa_1(A_0 + A_2(1 - \nu)\sigma^2 + A_3\nu_\alpha(1 - \rho_\alpha)) + \kappa_{0,i}}{1 - \kappa_{1,i}} \\
&+ \frac{\kappa_{1,i}(A_{2,i}(1 - \nu)\sigma^2 + A_{3,i}\nu_\alpha(1 - \rho_\alpha)) + \nu_i}{1 - \kappa_{1,i}} \\
&+ \frac{0.5(\gamma + (\theta - 1)\kappa_1 A_3 + \kappa_{1,i} A_{3,i})^2 \sigma_\alpha^2 + 0.5((\theta - 1)\kappa_1 A_2 + \kappa_{1,i} A_{2,i})^2 \sigma_w^2}{1 - \kappa_{1,i}}
\end{aligned}$$

**Deriving  $r_{f,t}$  :**

$$\mathbb{E}_t e^{\frac{\theta}{\psi} \log \delta - \frac{\theta}{\psi} \Delta c_{t+1} + (\theta - 1)r_{c,t+1} + r_{f,t}} = 1$$

So

$$\begin{aligned}
e^{-r_{f,t}} &= \mathbb{E}_t e^{\theta \log \delta - \frac{\theta}{\psi} \Delta c_{t+1} + (\theta-1)r_{c,t+1}} \\
&= e^{\mathbb{E}_t(\theta \log \delta - \frac{\theta}{\psi} \Delta c_{t+1} + (\theta-1)r_{c,t+1}) + 0.5 \mathbb{V}_t(\theta \log \delta - \frac{\theta}{\psi} \Delta c_{t+1} + (\theta-1)r_{c,t+1})} \\
&= e^{\theta \log \delta - \frac{\theta}{\psi} \mathbb{E}_t(\Delta c_{t+1}) + (\theta-1)\mathbb{E}_t r_{c,t+1} + 0.5 \mathbb{V}_t((-\frac{\theta}{\psi} \Delta c_{t+1} + (\theta-1)r_{c,t+1}))} \\
-r_{f,t} &= \theta \log \delta - \gamma(\nu_{cc} + x_t - \nu_\alpha(1 - \rho_\alpha) - \rho_\alpha \Delta \alpha_{cc,t}) + (\theta-1)(\kappa_0 - A_0 - A_1 x_t - A_2 \sigma_t^2 - A_3 \Delta \alpha_{cc,t}) \\
&\quad + (\theta-1)\kappa_1(A_0 + A_1 \rho_x x_t + A_2((1-\nu)\sigma^2 + \nu \sigma_t^2) + A_3(\nu_\alpha(1 - \rho_\alpha) + \rho_\alpha \Delta \alpha_{cc,t})) \\
&\quad + 0.5 \{(-\gamma + \pi(\gamma + (\theta-1)\kappa_1 A_3))^2 + ((\theta-1)\kappa_1 A_1)^2 \psi_x^2\} \sigma_t^2 \\
&\quad + 0.5(\gamma + (\theta-1)\kappa_1 A_3)^2 \sigma_\alpha^2 + 0.5((\theta-1)\kappa_1 A_2)^2 \sigma_w^2 \\
-r_{f,t} &= \theta \log \delta - \gamma(\nu_{cc} - \nu_\alpha(1 - \rho_\alpha)) + (\theta-1)(\kappa_0 - A_0) + (\theta-1)\kappa_1(A_0 + A_2(1-\nu)\sigma^2 + A_3 \nu_\alpha(1 - \rho_\alpha)) \\
&\quad + 0.5(\gamma + (\theta-1)\kappa_1 A_3)^2 \sigma_\alpha^2 + 0.5((\theta-1)\kappa_1 A_2)^2 \sigma_w^2 \\
&\quad + (-\gamma - (\theta-1)A_1 + (\theta-1)\kappa_1 A_1 \rho_x) x_t \\
&\quad + (-(\theta-1)A_2 + (\theta-1)\kappa_1 A_2 \nu + 0.5((-\gamma + \pi(\gamma + (\theta-1)\kappa_1 A_3))^2 + ((\theta-1)\kappa_1 A_1)^2 \psi_x^2)) \sigma_t^2 \\
&\quad + (\gamma \rho_\alpha - (\theta-1)A_3 + (\theta-1)\kappa_1 A_3 \rho_\alpha) \Delta \alpha_{cc,t}
\end{aligned}$$

Therefore :

$$r_{f,t} = A_{0,f} + A_{1,f} x_t + A_{2,f} \sigma_t^2 + A_{3,f} \Delta \alpha_{cc,t}$$

**Deriving  $\mathbb{E}_t r_{i,t+1}$  :**

$$\begin{aligned}
\mathbb{E}_t r_{i,t+1} &= \kappa_{0,i} + \kappa_{1,i} \mathbb{E}_t z_{i,t+1} - A_{0,i} - A_{1,i} x_t - A_{2,i} \sigma_t^2 - A_{3,i} \Delta \alpha_{cc,t} + \nu_i + \phi x_t + \phi_{\alpha,i} \Delta \alpha_{cc,t} \\
&= \kappa_{0,i} + \kappa_{1,i} \mathbb{E}_t (A_{0,i} + A_{1,i} x_{t+1} + A_{2,i} \sigma_{t+1}^2 + A_{3,i} \Delta \alpha_{cc,t+1}) \\
&\quad - A_{0,i} - A_{1,i} x_t - A_{2,i} \sigma_t^2 - A_{3,i} \Delta \alpha_{cc,t} + \nu_i + \phi_i x_t + \phi_{\alpha,i} \Delta \alpha_{cc,t} \\
&= \kappa_{0,i} + \kappa_{1,i} A_{0,i} + \kappa_{1,i} A_{1,i} \rho_x x_t + \kappa_{1,i} A_{2,i} ((1-\nu^2)\sigma^2 + \nu \sigma_t^2) \\
&\quad + \kappa_{1,i} A_{3,i} (\nu_\alpha(1 - \rho_\alpha) + \rho_\alpha \Delta \alpha_{cc,t}) - A_{0,i} - A_{1,i} x_t - A_{2,i} \sigma_t^2 - A_{3,i} \Delta \alpha_{cc,t} + \nu_i + \phi_i x_t + \phi_{\alpha,i} \Delta \alpha_{cc,t} \\
&= \kappa_{0,i} + \kappa_{1,i} A_{0,i} + \kappa_{1,i} A_{2,i} (1-\nu)\sigma^2 + \kappa_{1,i} A_{3,i} \nu_\alpha(1 - \rho_\alpha) - A_{0,i} + \nu_i \\
&\quad + (-A_{1,i} + \phi_i + \kappa_{1,i} A_{1,i} \rho_x) x_t + (-A_{2,i} + \kappa_{1,i} A_{2,i} \nu) \sigma_t^2 + (-A_{3,i} + \phi_{\alpha,i} + \kappa_{1,i} A_{3,i} \rho_\alpha) \Delta \alpha_{cc,t} \\
&= B_0 + B_1 x_t + B_2 \sigma_t^2 + B_3 \Delta \alpha_{cc,t}
\end{aligned}$$

The innovation in the market return is :

$$r_{i,t+1} - \mathbb{E}_t r_{i,t+1} = \kappa_{1,i} A_{1,i} \psi_x \sigma_t \epsilon_{x,t+1} + \kappa_{1,i} A_{2,i} \sigma_w \epsilon_{\sigma,t+1} + \kappa_{1,i} A_{3,i} \sigma_\alpha \epsilon_{\alpha,t+1} + \kappa_{1,i} A_{3,i} \pi \sigma_t \epsilon_{cc,t+1} + \psi_i \sigma_t \epsilon_{i,t+1}$$

So the expected equity premium on any dividend paying asset  $i$  is given by :

$$\begin{aligned} \mathbb{E}_t(r_{i,t+1} - r_{f,t}) &= -Cov(r_{i,t+1} - \mathbb{E}_t r_{i,t+1}, m_{t+1} - \mathbb{E}_t m_{t+1}) - 0.5 \mathbb{V}_t(r_{i,t+1}) \\ &= \lambda_{m,x} \underbrace{\kappa_{1,i} A_{1,i} \psi_x}_{\beta_{i,x}} \sigma_t^2 + \lambda_{m,w} \underbrace{\kappa_{1,i} A_{2,i}}_{\beta_{i,w}} \sigma_w^2 + \lambda_{m,\alpha} \underbrace{\kappa_{1,i} A_{3,i}}_{\beta_{i,\alpha}} \sigma_\alpha^2 + \lambda_{m,cc} \underbrace{\kappa_{1,i} A_{3,i} \pi}_{\beta_{i,cc}} \sigma_t^2 - 0.5 \mathbb{V}_t(r_{i,t+1}) \end{aligned}$$

And

$$\begin{aligned} \mathbb{V}_t(r_{i,t+1}) &= \mathbb{V}_t(\kappa_{1,i} z_{i,t+1} + \Delta d_{i,t+1}) \\ &= (\kappa_{1,i}^2 A_{1,i}^2 \psi_x^2 + \pi^2 \kappa_{1,i}^2 A_{3,i}^2 + \psi_i^2) \sigma_t^2 + \kappa_{1,i}^2 A_{2,i}^2 \sigma_w^2 + \kappa_{1,i}^2 A_{3,i}^2 \sigma_\alpha^2 \\ &= (\beta_{i,x}^2 + \beta_{i,cc}^2 + \psi_i^2) \sigma_t^2 + \beta_{i,w}^2 \sigma_w^2 + \beta_{i,\alpha}^2 \sigma_\alpha^2 \end{aligned}$$
